Appendix

The optimal strategy is by applying Fibonacci numbers

$$F_n = \{1, 2, 3, 5, 8, 13, \dots, F_n = F_{n-1} + F_{n-2}\}$$

suppose we have a set of discrete points $\{1, 2, 3, \dots, m = F_n - 1\}$, and we begin the searching by evaluating at the points F_{n-2} and F_{n-1} .

if $f(F_{n-2}) < f(F_{n-1})$, then the sub-problem is $\{F_{n-2} + 1, \dots, F_n - 1\}$ with $f(F_{n-1})$ has already been evaluated, thus a problem with $F_n - 1$ elements needs $n - 1$ evaluations to solve.

Lattice Search: Fibonacci Numbers

$$F_n = \{1, 2, 3, 5, 8, 13\}$$

For $m = F_6 - 1 = 12$, 5 evaluations are enough to reach the maximal value.

after each step, we got a sub-problem with $F_{n-1} - 1$ points. 15 / 54

Stopping and
Condition

Appendix

A more common problem is searching for the maximum on a continuum. so without losing generality, we set the interval $(0,1)$.

Divided the interval and use lattice search by placing m points in the interval, the set is

$$\{0, \frac{1}{m-1}, \frac{2}{m-1}, \dots, 1\}.$$

First two points

$$\lim \frac{F_{n-2}-1}{F_{n-1}} \text{ and } \lim \frac{F_{n-1}-1}{F_n-1}$$

Golden Section

Introduction
to
Optimization
and Nonlinear
Equations

Zeyu Lu &
Yuqiu Yang

Safe
Univariate
Methods:

Root finding

Stopping and
Condition

Appendix

And since we knew that the lattice search is defined by the first two evaluations, let m goes to infinity, then

$$\text{set } \lim \frac{F_{n-1}}{F_n} = \phi, \text{ so that } \lim \frac{F_n}{F_{n-1}} = \frac{1}{\phi} = \lim \frac{F_{n-2} + F_{n-1}}{F_{n-1}} = \phi + 1$$

$$\phi^2 + \phi + 1 = 0, \phi = \frac{\sqrt{5}-1}{2} \approx .618$$

which also known as the golden ratio. thus the starting points of the search are

$$X_1 = \phi^2 \approx 0.382, X_2 = \phi \approx 0.618$$

The limit of the lattice search is called the golden section search.

Golden Section

$$\text{Unimodal Function}(x) = -(x - 0.4)^2 + 0.36$$

After the first step, the uncertainty of interval is $(0, \phi)$ and the point $\phi^2 = 0.382$ has already been evaluated. Noticed it is also the right point in the second step, which is very similar to lattice search, and we only need to evaluate one more point at $\phi^3 \approx 0.236$.

Bisection

and Nonlinear
Equations

Zeyu Lu &
Yuqiu Yang

Safe
Univariate
Methods:

Root finding

Stopping and
Condition

Appendix

Fibonacci search is less restrictive, since the derivative of the function f doesn't need to exist, but suppose the derivative of the function f is available, which would convert the problem from finding maximum of a unimodal function to finding the root of a monotone function g on the same interval

suppose $g(x)$ is defined on interval (a, b) , and let $g(a) < 0 < g(b)$. with a single evaluation at $g(\frac{a+b}{2})$, the uncertainty of interval will be halved.

Root finding

Stopping and
Condition

Appendix

The more common problem is finding a root for a single nonlinear equation $g(x) = 0$.

for function g , set its derivative as g' , we have

$$g_t(x) = g(x_{old}) + g'(x_{old})(x - x_{old})$$

$g_t(x) = 0$ is at

$$x_{new} = x_{old} - \frac{g(x_{old})}{g'(x_{old})}$$

by using n , the iteration formula is:

$$x_{n+1} = x_n - \frac{g(x_n)}{g'(x_n)}$$

Methods:

Root finding

Stopping and
Condition

Appendix

Let $int(x_0, x_1, \dots, x_n)$: the smallest interval that contains x_0, \dots, x_n

According to Newton's interpolation formula, we have

$$g(x) = g(x_n) + (x - x_n)g[x_{n-1}, x_n] + \frac{1}{2}(x - x_n)(x - x_{n-1})g''(\xi)$$

$$\text{where } g[x_{n-1}, x_n] = \frac{g(x_n) - g(x_{n-1})}{x_n - x_{n-1}}, \text{ and } \xi \in int(x, x_n, x_{n-1})$$

By the Secant Method, we have

$$x_{n+1} = x_n - g(x_n) \frac{x_n - x_{n-1}}{g(x_n) - g(x_{n-1})} \Rightarrow$$

$$0 = g(x_n) + (x_{n+1} - x_n)g[x_{n-1}, x_n]$$

The Secant Method: Order of Convergence

Introduction
to
Optimization
and Nonlinear
Equations

Zeyu Lu &
Yuqiu Yang

Safe
Univariate
Methods:

Root finding

Stopping and
Condition

Appendix

Let the root the Secant Method approaches be c , then

$$0 = g(c) - g(x_n) - (x_{n+1} - x_n)g[x_{n-1}, x_n] = \\ g[x_{n-1}, x_n](c - x_{n+1}) + \frac{1}{2}(c - x_n)(c - x_{n-1})g''(\xi)$$

By the mean value theorem, we have

$$g[x_{n-1}, x_n] = g'(\eta), \eta \in (x_{n-1}, x_n)$$

Let $\epsilon_n = c - x_n$, we get $0 = g'(\eta)\epsilon_{n+1} + \frac{1}{2}\epsilon_n\epsilon_{n-1}g''(\xi) \Rightarrow$

$$\epsilon_{n+1} = \frac{g''(\xi)}{2g'(\eta)}\epsilon_n\epsilon_{n-1}$$

The Secant Method: Order of Convergence

Introduction
to
Optimization
and Nonlinear
Equations

Zeyu Lu &
Yuqiu Yang

Safe
Univariate
Methods:

Root finding

Stopping and
Condition

Appendix

Now suppose the Secant Method converges, then when $n \rightarrow \infty$, $\xi \approx c$ and $\eta \approx c$. Let $C = \left| \frac{g''(c)}{2g'(c)} \right|$, then $|\epsilon_{n+1}| = C|\epsilon_n||\epsilon_{n-1}|$

To find the order of convergence, we find M and p such that $|\epsilon_{n+1}| \approx M|\epsilon_n|^p$, where p is the convergence order.

$$M|\epsilon_n|^p = C(M|\epsilon_{n-1}|^p)|\epsilon_{n-1}| \Rightarrow |\epsilon_n| = C|\epsilon_{n-1}|^{(1+p)/p}$$

This implies $p = (1 + p)/p \Rightarrow p = 1 + \phi \approx 1.618$

Since the exponent 1.618 lies between 1 (linear convergence) and 2 (quadratic convergence), the convergence rate of the Secant Method is called *superlinear*.

Appendix

Like the Bisection Method, the Regula Falsi is “safe”. However, from the previous example, we see that this method is in general a first-order method.

Especially, if $g(x)$ is convex on $[x_0, x_1]$, then

$$|\epsilon_{n+1}| \approx C|\epsilon_n||\epsilon_0| = C'|\epsilon_n|$$

where $C = \frac{g''(c)}{2g'(c)}$

The Regula Falsi Method tends to retain one end-point for several iterations. As a result, it can be a good “start” method or a part of a “hybrid” method, but it should not be used near a root.

Illinois Algorithm: Building on Regula Falsi

Introduction

Appendix

Recall the errors of the Secant Method satisfy:

$$\epsilon_{n+1} = \frac{g''(\xi)}{2g'(\eta)} \epsilon_n \epsilon_{n-1}.$$

If g'' is continuous, then when the Illinois Algorithm gets into a sufficient small neighborhood of the root c , we can assume g' and g'' have constant sign.

This implies that $\frac{\epsilon_{n+1}}{\epsilon_n \epsilon_{n-1}}$ also has constant sign.

Since $g_{n-1}g_n < 0 \Rightarrow \epsilon_{n-1}\epsilon_n < 0$, we then necessarily have the sign of ϵ_n 's follow one of the two schemes:

$\cdots + - + + - + + - + \cdots$

or

$\cdots + - - + - - + - - \cdots$

Appendix

Previous analysis shows that asymptotically, an end-point will be retained twice in consecutive three iterations.

In other words, we will perform the Illinois step (halving the function value) once every third time.

Further asymptotic analysis shows that an Illinois step has

$$\epsilon_{n+1} \approx -\epsilon_n$$

Putting the pieces together, we have

$$\epsilon_{n+1} = -\epsilon_{n-1} \Rightarrow \epsilon_{n+1} = -C\epsilon_{n-1}^2 \Rightarrow \epsilon_{n+2} = C^2\epsilon_{n-1}^3$$

Via finding p such that $|\epsilon_n| = M|\epsilon_{n-1}|^p$, we get

$$\frac{3}{p^2} = p \Rightarrow p \approx 1.44$$

Successive Parabolic Interpolation

Recall the Newton's Method for optimization can be written as

$$x_{n+1} = x_n - \frac{f'(x_n)}{f''(x_n)}$$

The essence of Newton's Method is locally approximating a function via a sequence of parabolas.

If f' or f'' is hard to find, the Successive Parabolic Interpolation Method can be used to find the extremum.

In each iteration, we fit a parabola to 3 unique points and replace the “oldest” one with the extremum of the fitted parabola.

Stopping and Condition

Three options for termination

1 Too many steps

- Usually indicate a serious error in problem specification

2 No change in x or No change in the function values

- Need to check if a root or an extremum is being approached
- Root finding: in some cases, no x will produce $g(x)$ “close” to 0
- Root finding: at some function value, there may appear to be multiple roots
- Both absolute change $|x_{n+1} - x_n| < \epsilon_x$ and relative change $||x_{n+1} - x_n| < |x_n|\epsilon_x|$ can be used for x .
- For g only absolute change for root finding. Relative change is appropriate with optimization.

Given $n + 1$ distinct pairs

$\{(x_0, g(x_0)), (x_1, g(x_1)), \dots, (x_n, g(x_n))\}$, we will define:

$int(x_0, x_1, \dots, x_n)$: the smallest interval that contains x_0, \dots, x_n

The divided differences

$$g[x_0, x_1, \dots, x_j, x] = \frac{g[x_0, x_1, \dots, x_{j-1}, x] - g[x_0, x_1, \dots, x_j]}{x - x_j}$$

, and

$$g[x_0, x] = \frac{g(x) - g(x_0)}{x - x_0}$$

Given $n + 1$ distinct pairs

$\{(x_0, g(x_0)), (x_1, g(x_1)), \dots, (x_n, g(x_n))\}$, we can interpolate these points using a polynomial $q(x)$ of degree n .

Specifically,

$$q(x) = g(x_0) + \sum_{j=1}^n g[x_0, x_1, \dots, x_j] \prod_{i=0}^{j-1} (x - x_i)$$

, with the remainder

$$g(x) - q(x) = \frac{g^{n+1}(\xi) \prod_{i=0}^n (x - x_i)}{(n+1)!}$$

, where $\xi \in \text{int}(x_0, x_1, \dots, x_n, x)$
